## Section outline

Why nonparametrics?

- sometimes just interested in the distribution
- sometimes this is the first stage and we want to integrate
- sometimes want to do something semiparametric

In this section, we are interested in estimating the **density** f(x) under minimal assumptions.

Richard L. Sweeney

Density Estimation

Validation

Auctions

parametric Regression Multivariate Kernels Local linear Basis Expansions

Semiparametri

References

# Let's start with the histogram

One of the more successful and popular uses of nonparametric methods is estimating the density or distribution function f(x) or F(x).

$$\hat{f}_{HIST}(x_0) = \frac{1}{N} \sum_{i=1}^{N} \frac{\mathbf{1}(x_0 - h < x_i < x_0 + h)}{2h}$$

 Divide the dataset into bins, count up fraction of observations in each bins

Semiparametrio

References

Let's rewrite the histogram estimator

$$\hat{f}_{HIST}(x_0) = \frac{1}{Nh} \sum_{i=1}^{N} K\left(\frac{x_i - x_0}{h}\right)$$

Where 
$$K(z) = \frac{1}{2} \cdot \mathbf{1}(|z| < 1)$$

# Density estimator interpretation

- for each observation, there is probability mass 1 to spread around
- use the function  $K(\cdot)$  and smoothing parameter h to choose how to allocate this mass
- then, for any given  $x_0$ , sum over these functions that spread out mass, and normalize by dividing by N

References

## Smooth Kernels

We call  $K(\cdot)$  a Kernel function and h the bandwidth. We usually assume

- (1) K(z) is symmetric about 0 and continuous.
- $\label{eq:continuous} \mbox{\scriptsize \ifomtheta} \int K(z)dz = 1, \ \int zK(z)dz = 0, \ \int |K(z)|dz < \infty.$
- $\textcircled{\textbf{m}}$  Either (a) K(z)=0 if  $|z|\geq z_0$  for some  $z_0$  or (b)  $|z|K(z)\to 0$  as  $|z|\to \infty$ .
- $\bigvee \int z^K(z)dz = \kappa$  where  $\kappa$  is a constant.

Usually we choose a smooth, symmetric K. But a common nonsmooth choice: K(x)=(|x|<1/2) gives the histogram estimate.

## Some Common Kernels

**Table 9.1.** Kernel Functions: Commonly Used Examples<sup>a</sup>

Kernel	Kernel Function K(z)	δ
Uniform (or box or rectangular)	$\frac{1}{2} \times 1( z  < 1)$	1.3510
Triangular (or triangle)	$(1- z ) \times 1( z  < 1)$	_
Epanechnikov (or quadratic)	$\frac{3}{4}(1-z^2) \times 1( z  < 1)$	1.7188
Quartic (or biweight)	$\frac{15}{16}(1-z^2)^2 \times 1( z <1)$	2.0362
Triweight	$\frac{35}{32}(1-z^2)^3 \times 1( z <1)$	2.3122
Tricubic	$\frac{70}{81}(1- z ^3)^3 \times 1( z <1)$	_
Gaussian (or normal)	$(2\pi)^{-1/2} \exp(-z^2/2)$	0.7764
Fourth-order Gaussian	$\frac{1}{2}(3-z)^2(2\pi)^{-1/2}\exp(-z^2/2)$	_
Fourth-order quartic	$\frac{15}{32}(3 - 10z^2 + 7z^4) \times 1( z  < 1)$	_

<sup>&</sup>lt;sup>a</sup> The constant  $\delta$  is defined in (9.11) and is used to obtain Silverman's plug-in estimate given in (9.13).

# Mean and Variance of $\hat{f}(x_0)$

Assume that the derivative of f(x) exists and is bounded, and  $\int zK(z)dz=0$ 

Then the estimator has bias

$$b(x_0) = E\left[\hat{f}(x_0)\right] - f(x_0) = \frac{1}{2}h^2f''(x_0)\int z^2K(z)dx$$

The variance of the estimator is

$$V\left[\hat{f}(x_0)\right] = \frac{1}{Nh}f(x_0)\int K(z)^2 dz \left\{+o(\frac{1}{Nh})\right\}$$

So, unsurprisingly, the bias is *increasing* in h, and the variance is *decreasing* in h.

### How to Choose h

- We want both bias and variance to be as small as possible, as usual.
- In parametric estimation, it is not a problem: they both go to zero as sample size increases.
- In nonparametric estimation reducing h reduces bias, but increases variance; how are we to make his trade off?
- Note that how we set h is going to be much more important than the choice of  $K(\cdot)$

References

# Mean Integrated Square Error

ullet Start with the *local* performance at  $x_0$ 

$$MSE\left[\hat{f}(x_0)\right] = E\left[\left(\hat{f}(x_0) - f(x_0)\right)^2\right]$$

Calculate the *integrated* (as opposed to expected) squared error

$$\int \left( \hat{f}(x) - f(x) \right)^2 dx = - \int \mathsf{bias}^2 \left( \hat{f}(x) \right) + \mathsf{var} \left( \hat{f}(x) \right) dx$$

• Simple approximate expression (symmetric order 2 kernels):

$$(\mathsf{bias})^2 + \mathsf{variance} = Ah^4 + B/nh$$

with 
$$A = \int (f''(x))^2 (\int u^2 K)^2 / 4$$
 and  $B = f(x) \int K^2$

# Optimal bandwidth

• The AMISE is

$$Ah^4 + B/nh$$

• Minimize by taking the FOC

$$h_n^* = \left(\frac{B}{4An}\right)^{1/5}$$

- bias and standard error are both in  $n^{-2/5}$
- and the AMISE is  $n^{-4/5}$ —not 1/n as it is in parametric models.
- But: A and B both depend on K (known) and f(y) (unknown), and especially "wiggliness"  $\int (f'')^2$  (unknown, not easily estimated). Where do we go from here?

Richard L. Sweeney

Density Estimation

Cross-Validation

Example: Auctions

Regression

Multivariate
Kernels

Local linear

Basis Expansions

Semiparametrio

Reference

# Optimal bandwidth

Can be shown that the optimal bandwidth is

$$h* = \delta \left( \int f''(x_0)^2 dx_0 \right)^{-0.2} N^{-0.2}$$

where  $\delta$  depends on the kernel used (Silverman 1986) [these  $\delta$ 's are given in the kernel table]

Note the "optimal" kernel is Epanechnikov, although the difference is small.

## Silverman's Rule of Thumb

• If f is normal with variance  $\sigma^2$  (may not be a very appropriate benchmark!), the optimal bandwidth is

$$h_n^* = 1.06\sigma n^{-1/5}$$

• In practice, typically use Silverman's plug-in estimate:

$$h_n^* = 0.9 * \min(s, IQ/1.34) * n^{-1/5}$$

where IQ=interquartile distance

• Investigate changing it by a reasonable multiple.

This tends to work pretty well. But can we do better?

# Why not search for optimal h in our data?

- Know we want to minimize MISE.
- ullet One option is to find the h that minimizes it in sample
  - Loop through increments of h
  - Calculate MISE
- Example: Old Faithful R data
  - Waiting time between eruptions and the duration of the eruption for the Old Faithful geyser in Yellowstone National Park, Wyoming, USA.
  - See R code in this folder.

## Cross-validation

ullet General concept in the whole of nonparametrics: choose h to minimize a criterion CV(h) that approximates

$$AMISE(h) = \int E(\hat{f}_n(x) - f(x))^2 dx.$$

- Usually programmed in metrics software. If you can do it, do it on a subsample, and rescale.
- CV tries to measure what the expected out of sample (OOS or EPE) prediction error of a new never seen before dataset.
- The main consideration is to prevent overfitting.
  - In sample fit is always going to be maximized by the most complicated model.
  - OOS fit might be a different story.
  - ie 1-NN might do really well in-sample, but with a new sample might perform badly.

Richard L. Sweeney Sample Splitting/Holdout Method and CV

Density Estimation

Cross Validation is actually a more complicated version of sample splitting that is one of the organizing principles in machine learning literature.

Cross-Validation

Training Set This is where you estimate parameter values.

Regression
Multivariate
Kernels

Basis Expansions

Validation Set This is where you choose a model- a bandwidth h or tuning parameter  $\lambda$  by computing the error.

Semiparametri Test Set You are only allowed to look at this after you have chosen a model. Only Test Once: compute the error again on fresh data.

References

- Conventional approach is to allocate 50-80% to training and 10-20% to Validation and Test.
- Sometimes we don't have enough data to do this reliably.

## k-fold Cross Validation

- Break the dataset into k equally sized "folds" (at random).
- Withhold i=1 fold
  - Estimate the model parameters  $\hat{\theta}^{(-i)}$  on the remaining k-1 folds
  - Predict  $\hat{y}^{(-i)}$  using  $\hat{\theta}^{(-i)}$  estimates for the ith fold (withheld data).
  - Compute  $MSE_i = \frac{1}{k \cdot N} \sum_j (y_j^{(-i)} \hat{y}_j^{(-i)})^2$ .
  - Repeat for  $i = 1, \ldots, k$ .
- Construct  $\widehat{MSE}_{k,CV} = \frac{1}{k} \sum_{i} MSE_{i}$

## Cross Validation

- Main advantage of cross validation is that we use all of the data in both estimation and in validation.
  - For our purposes validation is mostly about choosing the right bandwidth or tuning parameter.
- We have much lower variance in our estimate of the OOS mean squared error.
  - Hopefully our bandwidth choice doesn't depend on randomness of splitting sample.

Example:

parametric
Regression
Multivariate
Kernels
Local linear
Basis Expansions

Semiparametrio

References

## Test Data

- In Statistics/Machine learning there is a tradition to withhold 10% of the data as Test Data.
- This is completely new data that was not used in the CV procedure.
- The idea is to report the results using this test data because it most accurately simulates true OOS performance.
- We don't do much of this in economics. (Should we do more?)

Richard L. Sweeney

Density Estimation

Cross-Validation Example:

Nonparametric
Regression
Multivariate
Kernels

## Local Bandwidths

If you only care about f(y) at some given point, then

$$A = f''(y)^2 \left( \int u^2 K \right)^2 / 4 \text{ and } B = f(y) \int K^2.$$

So in a low-density region, worry about variance and take h larger. In a curvy region, worry about bias and take h small.

# Higher-Order Kernels

- K of order r iff  $\int x^j K(x) dx = 0$  for j < r and  $\int x^r K(x) dx \neq 0$ . Try r > 2?
- The beauty of it: bias in  $h^r$  if f is at least  $C^r$ ...so AMISE can be reduced to  $n^{-r/(2r+1)}$ , almost  $\sqrt{n}$ -consistent if r is large.
- But gives wiggly (and sometimes negative) estimates  $\rightarrow$  leave them to theorists.

## Back to the CDF

Since now we have estimated the density with

$$\hat{f}_n(x) = \frac{1}{nh} \sum_{i=1}^n K\left(\frac{x - x_i}{h}\right),$$

a natural idea is to integrate; let  $\mathcal{K}(x) = \int_{-\infty}^x K(t) dt$ , try

$$\hat{F}_n(y) = \frac{1}{n} \sum_{i=1}^n \mathcal{K}\left(\frac{y - y_i}{h}\right)$$

as a reasonable estimator of the cdf in y.

Very reasonable indeed:

- when  $n\longrightarrow\infty$  and h goes to zero (at rate  $n^{-1/3}$  ...) it is consistent at rate  $\sqrt{n}$
- it is nicely smooth
- by construction it accords well with the density estimator
- ... it is a much better choice than the empirical cdf.

# Example application: Auctions

- Why auctions?
- Great introduction to structural approach. Arguably the most successful application.
- Auctions are an example of a game with assymetric information: participants know the primitives of the game, but do not know their rivals exact valuations.
- By imposing rationality/ profit maximization, we can recover the distribution of values.
- Can then run counterfatuals
- Example: Asker (AER 2008) stamp cartel

For more detail, check out Chris Conlon's slides in this folder, or John Asker's PhD lecture notes.

Let's consider the first price sealed bid (FPSB) auction

- bidders have **private information** (or type) scalar rv  $X_i$  with realization  $x_i$
- signals are informative: dE[U|x]/dx > 0
- ullet given their signal, they make a bid  $b_i$
- if its the highest bid, recieve utility  $[U|x_i,x_{-i}]-b_i$
- else get 0
- note that if we assume values are **independent**, we get  $E[U|x_i,x_{-i}]=E[U|x_i]$

This introduces a tradeoff in first price auctions: Increasing the bid increases the probability of winning; but reduces your net utility from the object.

Sweeney

# Can find bid as a function of primitives

$$v(x_i, \mathbf{x_i}; N) = b_i + \frac{G_{M_i|B_i}(b_i|b_i; N)}{g_{M_i|B_i}(b_i|b_i; N)}$$

where  $G_{M_i \mid B_i}$  and  $g_{M_i \mid B_i}$  are the CDF and PDF of the max bids given  $b_i$  and N

- we are typically interested in the LHS
- RHS is stuff we can observe or compute
- nice linear structure makes this easy to work with
- Guerre, Perrigne and Vuong (2000): can leverage assumption of equilibrium best response and invertibility of b to recover v

References

# Estimation strategy I

[Assumption: FPSB with symmetric IPV]

1 Leverage independence assumption:

$$G_{M_i|B_i}(m_i|b_i;N) = G_{M_I|n}$$
  
=  $Pr(\max_{j \neq i} B_j \leq m_i|n)$ 

2 Value equation becomes

$$u = b + \frac{G_B(b|n)}{(n-1)g_B(b|n)}$$

where  $G_B$  and  $g_B$  are now the marginal distribution of equilibrium bids and the densities in n bidder auctions

### Nonparametric Regression

- Often we're interested in  $E[Y_i|X_i=x]$
- ullet If X is discrete, can just average for each value
- But often times we want to smooth across values of X
  - Each bin could have small n. [Likely if X has many dimensions]
  - X could be continuous
- One option is to pick a parametric functional form y=f(x). But often hard to think about how sensible these assumptions are (and what they impose on the economics of the problem)
- An alternative is to extend the concepts of nonparametric density estimation

#### Alternative

- Lots of potential alternatives to our decision rule.
- A simple idea is to hold a majority vote of neighboring points

$$Y^* = \frac{1}{k} \sum_{x_{-i} \in N_k(x)} y_i$$

- How many parameters does this model have: None? One? k?
- Technically it has something like N/k.
- As  $N \to \infty$  this means we have an infinite number of parameters! (This is a defining characteristic of non-parametrics).

### Comparisons

- What would happen if  $K \to N$ ?
- The k-NN model is locally constant.
- The k-NN approach tends to be really bumpy which can be undesirable.
- The OLS model is globally linear (is this always true?)

References

### What about?

- If we fixed the fact that there are discrete jumps in who is in the neighborhood by smoothly weighting observations and varying those weights instead (Kernels).
- Another drawback of k-NN is that we consider distance in each X dimension on the same scale, perhaps we could rescale the data to improve our "closeness" measure.
- Instead of fitting a constant locally, we fit a linear function locally (Lowess).
- Instead of using a global linear approximation in OLS use a more flexible nonlinear one.
- There is a bias/variance tradeoff. explain.

Richard L. Sweeney

Density Estimation

Validation Example:

Auctions
Non-

parametric

### Bias Variance Decomposition

We can decompose any estimator into two components

$$\underbrace{E[(y-\hat{f}(x))^2]}_{MSE} = \underbrace{\left(E[\hat{f}(x)-f(x)]\right)^2}_{Bias^2} + \underbrace{E\left[\left(\hat{f}(x)-E[\hat{f}(x)]\right)^2\right]}_{Variance}$$

- In general we face a tradeoff between bias and variance.
- In k-NN as k gets large we reduce the variance (each point has less influence) but we increase the bias since we start incorporating far away and potentially irrelevant information.
- In OLS we minimize the variance among unbiased estimators assuming that the true f is linear and using the entire dataset.

# Curse of Dimensionality

Take a unit hypercube in dimension p and we put another hypercube within it that captures a fraction of the observations r within the cube

- Since it corresponds to a fraction of the unit volume, r each edge will be  $e_p(r)=r^{1/p}$ .
- $e_{10}(0.01) = 0.63$  and  $e_{10}(0.1) = 0.80$ , so we need almost 80% of the data to cover 10% of the sample!
- If we choose a smaller r (include less in our average) we increase variance quite a bit without really reducing the required interval length substantially.

# Curse of Dimensionality

FIGURE 2.6. The curse of dimensionality is well illustrated by a subcubical neighborhood for uniform data in a unit cube. The figure on the right shows the side-length of the subcube needed to capture a fraction r of the volume of the data, for different dimensions p. In ten dimensions we need to cover 80% of the range of each coordinate to capture 10% of the data.

# Curse of Dimensionality

Don't worry, it only gets worse:

$$d(p, N) = \left(1 - \left(\frac{1}{2}\right)^{1/N}\right)^{1/p}$$

- ullet d(p,N) is the distance from the origin to the closest point.
- N=500 and p=10 means d=0.52 or that the closest point is closer to the boundary than the origin!
- Why is this a problem?
- In some dimension nearly every point is the closest point to the boundary – when we average over nearest neighbors we are extrapolating not interpolating.

### Back to Bias - Variance

What minimizes MSE?

$$f(x_i) = E[Y_i|X_i]$$

- Seems simple enough (but we are back where we started).
- How do we compute the expectation ?
- k-NN tries to use local information to estimate conditional mean
- OLS uses entire dataset and adds structure  $y=x\beta$  to the problem.
- A natural middleground point is to use a smoother that weights "close" observations more than "far" ones.

# Common weights

Consider the following local weighted average estimator:

$$\hat{m}(x_0) = \sum_{i=1}^{N} w_{i0,h} y_i$$

where  $w_{i0,h} = w(x_i, x_0, h)$  and  $\sum_i w_{i0,h} = 1$ .

Rearranging, can see that OLS uses the following weights

$$\hat{m}_{OLS}(x_0) = \sum_{i=1}^{N} \left\{ \frac{1}{N} + \frac{(x_0 - \bar{x})(x_i - \bar{x})}{\sum_{j} (x_j - \bar{x})^2} \right\} y_i$$

CT note that these weights can actually *increase* with the distance between  $x_0$  and  $x_i$ ! (for example if  $x_i > x_0 > \bar{x}$ )

# k-NN is simply a running average

$$\hat{m}_k(x_0) = \frac{1}{k} (y_{i-(k-1)/2} + \dots + y_{i+(k-1)/2})$$

Can immediately see that this will not be great at the end points.

For the smallest and largest x, the average is one sided. This is the **boundary problem**.

### Nonparametric Regression

Of course, we could also average all the observations within some bandwidth  $\boldsymbol{h}$ 

Nadaraya-Watson:

$$\hat{m}_n(x) = \frac{\sum_{i=1}^n y_i K\left(\frac{x-x_i}{h}\right)}{\sum_{i=1}^n K\left(\frac{x-x_i}{h}\right)}.$$

where  $K(\cdot)$  is a kernel weighting function as above.

Again, bias in  $h^2$  and variance in 1/nh if  $p_x=1$ .

References

Plug-in estimates work badly here.

In most cases leave one out cross-validation is feasible

Can be shown that this amounts to

$$\min_{h} CV(h) = \sum_{i=1}^{N} \left( \frac{y_i - \hat{m}(x_i)}{1 - \left[ w_{ii,h} / \sum_{j} w_{ji}, h \right]} \right)^2$$

So not that hard: for each h, only need to compute one weighted average  $\hat{m}(x_i)$  for each N.

References

#### Multivariate Kernels

Typically we are interested in more than one regressor

$$y_i = m(x_{1i}, ..., x_{ki})$$

the NW kernel estimator extends naturally to  $\boldsymbol{k}$  dimensions

$$\hat{m}(\mathbf{x_0}) = \frac{\sum_{i=1}^{N} y_i K\left(\frac{\mathbf{x_1} - \mathbf{x_0}}{h}\right)}{\sum_{i=1}^{N} K\left(\frac{\mathbf{x_1} - \mathbf{x_0}}{h}\right)}.$$

where we just use a mutivariate kernel.

If you rescale by dividing by the standard deviation, you can even use a common bandwidth.

# Density/Distribution Estimation

One of the more successful and popular uses of nonparametric methods is estimating the density or distribution function f(x) or F(x).

- Estimating the CDF is easy and something you have already done
- Q-Q plots, etc.

$$\hat{F}_{ECDF}(x_0) = \frac{1}{N} \sum_{i=1}^{N} (x_i \le x_0)$$

• Differentiating to get density is unhelpful :  $F_{ECDF}'(x) = 0$  in most places.

# What if y is of dimension $p_y > 1$ ?

"Easy": use  $p_y$ -dimensional K (often a  $p_y$ -product of 1-dim kernels) and bandwidth h, and do

$$\hat{f}_n(y) = \frac{1}{nh_y^p} \sum_{i=1}^n K\left(\frac{y - y_i}{h}\right).$$

- 1st minor pitfall: the various dimensions may have very different variances, so use  $(h_1, \ldots, h_{p_n})$ .
- 2nd minor pitfall: they may be strongly correlated; then sphericize first.
- Major problem: next slide...

# The Curse of Dimensionality

- Computational cost increases exponentially.
- Much worse: to achieve precision  $\epsilon$  in dimension  $p_y$ , the number of observations you need increases as

$$n \simeq \epsilon^{-(2+p_y/2)}.$$

• The *empty space* phenomenon: if  $(y_1,\ldots,y_{p_y})$  all are iid uniform on [-1,1], then only  $n/(10^{p_y})$  observations on average have all components in [-0.1,0.1]. Bias still in  $h^2$ , but variance in  $1/nh^{p_y}$  now.

### Silverman's Table

Silverman (1986 book) provides a table illustrating the difficulty of kernel estimation in high dimensions. To estimate the density at 0 of a N(0,1) with a given accuracy, he reports:

Dimensionality Required	Sample Size
1	4
2	19
5	786
7	10,700
10	842,000

Not to be taken lightly... in any case convergence with the optimal bandwidth is in  $n^{-2/(4+p_y)}$  now—and Silverman's rule of thumb for choosing  $h_n^*$  must be adapted too.

Richard L. Sweeney

# Usually we care about conditional densities

That is: we have covariates x, we want the density f(y|x). Again, "easy":

- $oldsymbol{0}$  get a kernel estimator of the joint density f(y,x);
- 2 and one of of the marginal density f(x);
- 3 then define

$$\hat{f}_n(y|x) = \frac{\hat{f}_n(y,x)}{\hat{f}_n(x)} = \frac{\frac{1}{nh_y^{p_y}h_x^{p_x}} \sum_{i=1}^n K\left(\frac{y-y_i}{h_y}\right) K\left(\frac{x-x_i}{h_x}\right)}{\frac{1}{h_y^{p_y}} \sum_{i=1}^n K\left(\frac{x-x_i}{h_x}\right)}.$$

But the joint density is  $(p_x + p_y)$  dimensional... and the curse strikes big time.

#### Back to one dimesion I

We can interpret the standard kernel estimator as estimating a constant regressino function  $g(\boldsymbol{x}) = m$ 

where

$$\hat{m} = \arg\min_{m_0} \sum_{i=1}^{N} K\left(\frac{x_i - x_0}{h}\right) \cdot (y_i - m_0)^2$$

Taking the FOC, we see that this yields

$$\hat{g}(x) = \hat{m} = \sum_{i=1}^{N} K\left(\frac{x_i - x_0}{h}\right) \cdot y_i / \sum_{i=1}^{N} K\left(\frac{x_i - x_0}{h}\right)$$

# Local Linear Regression I

This suggests other functions instead of constants (that is why we're interested in this regression in the first place!)

A natural option is local linear regression:

$$m(x) = \alpha + \beta(x - x_0)$$

where

$$(\hat{\alpha}, \hat{\beta}) = \arg\min_{m_0} \sum_{i=1}^{N} K\left(\frac{x_i - x_0}{h}\right) \cdot (y_i - \alpha + \beta(x_i - x_0))^2$$

Nonparametri Regression Multivariate

Kernels

Local linear

Basis Expansions

Semiparametrio

References

# Local Linear Regression II

#### Advantages:

- the bias becomes 0 if the true m(x) is linear.
- the coefficient of  $(x-x_i)$  estimates m'(x).
- behaves better in "almost empty" regions.

Disadvantages: hardly any, just do it! How?

Locally Weighted Scatterplot Smoothing (lowess)

- ullet uses a variable bandwidth  $h_{0,k}$
- tricubic kernel
- ullet downweights observations with large residuals (through N iterations)
- Output: robust to outliers, smooth, and better at boundaries
- In most packages, but can be

Richard L. Sweeney

### The Housing Market Impacts of Shale Gas Development

By Lucija Muehlenbachs, Elisheba Spiller, and Christopher Timmins

Using data from Pennsylvania and an array of empirical techniques to control for confounding factors, we recover hedonic estimates of property value impacts from nearby shale gas development that vary with water source, well productivity, and visibility. Results indicate large negative impacts on nearby groundwater-dependent homes, while piped-water-dependent homes exhibit smaller positive impacts, suggesting benefits from lease payments. Results have implications for the debate over regulation of shale gas development. (JEL L71, Q35, Q53, R31)

# Piecewise polynomials

- ullet First consider a single dimensional X
- ullet Divide f into contiguous intervals, and pick a function to represent y on each interval
- A natural starting point would be a piecewise constant function, broken up by boundary points  $\xi_1$  and  $xi_2$

$$h_1 = I(X < \xi_1); h_2 = I(\xi_1 < X < \xi_2); h_3 = I(\xi_2 < X)$$

- ullet This predicts the interval average for all X
- We can improve this by adding three additional basis functions:  $h_{m+3} = h_m(X)X$ .
- We can then make it continuous by

$$h_1 = 1$$
  
 $h_2 = X$   
 $h_3 = (X - \xi_1)_+$   
 $h_4 = (X - \xi_2)_+$

# Smooth splines

- We can improve this further by increasing the order of the local polynomial
- A common option is cubic splines:

$$h_1 = 1; h_2 = X; h_3 = X^2$$
  
 $h_4 = x^3; h_5(X - \xi_1)^3_+; h_6 = (X - \xi_2)^3_+$ 

- This is a six dimensional space: (3 regions) X (4 parameters per region) (2 knots) X (3 constraints per knot)
- In practice people never use higher than cubic
- Picking the knots is more subjective (use CV?)
- Also typically use B-splines (see HTF)

## Piecewise Cubic Polynomials

FIGURE 5.2. A series of piecewise-cubic polynomials, with increasing orders of continuity.

References

## Series or sieves

- This is a parametric approximation that becomes more accurate as the sample size increases
- Idea: we add regressors when we have more data, eventually providing an arbitrarily close approximation to the true regression function
- Polynomial Example:  $m(x; \beta_K) = \sum_{j=1}^K \hat{\beta}_j x^j$
- Given K, just estimate model using OLS
- In practice, you'll want to choose K using leave-one-out cross validation.

Note that simply polynomials often perform poorly in some parts of the data!

# Cubic Splines

Note that simply polynomials often perform poorly in some parts of the data!

Another common option is

$$\min_{m(.)} \sum_{i}^{N} (y_i - m(x_i))^2 + \lambda J \int (m''(x))^2 dx$$

where  $\lambda$  is a smoothing parameter and m is a cubic polynomial

Then we "obtain" the natural cubic spline with  $knots=(x_1,\ldots,x_n)$ :

- m is a cubic polynomial between consecutive  $x_i$ 's
- it is linear out-of-sample
- it is  $C^2$  everywhere.

"Consecutive" implies one-dimensional...harder to generalize to  $p_x>1.$

## Partial linear model

We'll focus on the most commonly used model: the **partial** linear model

$$y_i = X_i'\beta + g(Z_i) + e_i$$

We are interested in  $\beta$ , but g() is an unrestricted (unknown) function of z.

 $\label{eq:cov} \mbox{Identification requires } Cov[X,g(Z)] = 0$ 

Robinson (1988) showed that we can concentrate this g() out of the model.

Validation Example:

parametric
Regression
Multivariate
Kernels
Local linear
Basis Expansions

Semiparametrics

References

$$y_i = X_i'\beta + g(Z_i) + e_i$$

where  $e_i = y_i - E[y_i|X_i,Z_i]$ .

Take the conditional expectation

$$E[y_i|Z_i] = E[X_i|Z_i]'\beta + g(Z_i) + E[e_i|Z_i]$$

then note that  $E[e_i|Z_i]=E[E[e_i|X_i,Z_i]]=0$  Subtracting yields

$$y_i - E[y_i|Z_i] = (X_i - E[X_i|Z_i])'\beta + e_i$$

Richard L. Sweeney

Density Estimation

Example:

parametric
Regression
Multivariate
Kernels
Local linear

Basis Expansions
Semiparametrics

So this suggests a natural procedure:

- 1. Estimate the conditional expectations  $m_y(z)=E[y_i|Z_i]$  and  $m_x(z)=E[X_i|Z_i]$  separately (and flexibly) for each x using the methods discussed in the previous section.
- 2. Estimate  $\beta$  using OLS on the residuals

$$y_i - \hat{m}_y(z_i) = (X_i - \hat{m}_x(z_i))'\beta + e_i$$

Note: Yatchew (1997) suggest step 1 can be avoided entirely by simply sorting on z, and running the model in first-differences.
